Designing integrated photonics, especially to leverage Kerr-nonlinear optics, requires accurate and precise knowledge of the refractive index across the visible to infrared spectral ranges. Tantala (Ta_2O_5) is an emerging material platform for integrated photonics and nanophotonics that offers broadband ultralow loss, moderately high nonlinearity, and advantages for scalable and heterogeneous integration. We present refractive index measurements on a thin film of tantala, and we explore the efficacy of this data for group-velocity-dispersion (GVD) engineering with waveguide and ring-resonator devices. In particular, the observed spectral extent of supercontinuum generation in fabricated waveguides and the wavelength dependence of free spectral range (FSR) in optical resonators provide a sensitive test of our integrated photonics design process. Our work opens up new design possibilities with tantala, including with octave-spanning soliton microcombs. © 2021 Optical Society of America

Photonic-integrated circuits (PICs) of waveguide-based devices offer breakthrough opportunities for basic scientific investigations, applications with light–matter interactions, and commercial devices that are widely used. In particular, waveguide PICs provide tight optical confinement and group-velocity-dispersion (GVD) engineering that is ideal for nonlinear optics. Through the Kerr effect, PIC designers may leverage efficient wavelength conversion at low input power [1], generation of chip-scale optical frequency combs [2], and ultrabroad bandwidth supercontinua [3]. Several materials are suitable for nanophotonic nonlinear device design [4–7]. Silicon nitride has attracted attention as a complementary metal-oxide-semiconductor (CMOS) compatible $\chi^{(3)}$ nonlinear material with nonlinear index, $n_2 = 2.4 \times 10^{-19}$ m²/W [8], an order of magnitude greater than silicon dioxide [9]. Broadband knowledge of silicon nitride's optical properties enables the precise GVD engineering necessary for successful device design [10]. As a result, silicon nitride devices have generated chip-scale supercontinua spanning an octave or more [11,12], as well as chip-scale octave-spanning Kerr soliton optical frequency combs [13].

Here, we explore the refractive index and the GVD design space of tantalum pentoxide (Ta_2O_5, hereafter tantala), a promising, CMOS-compatible $\chi^{(3)}$ nonlinear material. Indeed, tantala offers superior material properties compared with silicon nitride, including a slightly higher nonlinear index $n_2 = 6.2 \times 10^{-19}$ m²/W, much lower residual stress (38 MPa), a smaller thermo-optic coefficient (8.8×10^{-6} 1/K), and a broader transparency window [14,15]. These factors, tantala's high index of refraction, and tantala's low temperature processing requirement make it an important integrated photonics platform for linear [16,17] and nonlinear applications [18–21].

Obtaining an accurate and precise understanding of the bulk material properties is critical for future PIC design, particularly using the ion-beam-sputtered tantala films that our previous work has shown offers low loss [14]. Previous reports of the index of refraction and absorption coefficient are available up to a wavelength of 1.8 µm [15,22], but they provide inconsistent results, making it challenging to accurately design tantala PICs. To better understand tantala's optical properties and to extend this information into the mid-infrared, we have measured the refractive index and absorption coefficient. We deposited an 800-nm-thick tantala layer on 3-µm-thick thermally oxidized silicon wafer, and J. A. Woollam Co. [23] measured the layer across the spectral ranges of 190–1700 nm and 1.7–39.2 µm using RC2 and IR-VASE ellipsometry instruments, respectively. The data were fit simultaneously across both spectral regions using a combination of Sellmeier, Tauc–Lorentz, and several Gaussian dispersion functions. Figure 1(a) shows the real index of refraction (n) and extinction coefficient (k) of tantala as a function of wavelength (λ) from 200 nm to 10 µm, where the complex index of refraction $\tilde{n} = n + i \cdot k$. In this spectral region, the real index of refraction is predominantly larger than 2, which provides a relatively large refractive index contrast with common cladding materials (e.g., air and silicon dioxide), and the absorption coefficient is relatively low over the range 320 nm to 8 µm. Equation (1) presents a third-order Sellmeier equation fit,

$$n^2 = 1 + \frac{0.033\lambda^2}{\lambda^2 - 0.368^2} + \frac{3.212\lambda^2}{\lambda^2 - 0.1639^2} + \frac{3.747\lambda^2}{\lambda^2 - 14.5^2}, \quad (1)$$
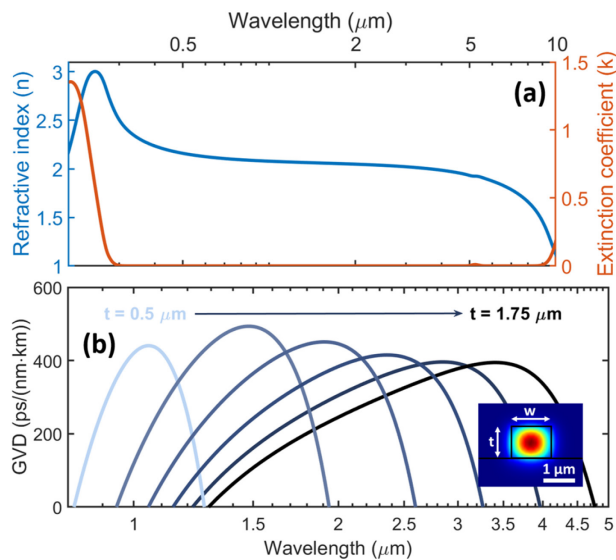

Fig. 1. (a) Refractive index (n) and extinction coefficient (k) data for tantala from 200 nm to 10 µm on a log wavelength scale. A broad transparency window is evident from 320 nm to 8 µm. (b) The simulated GVD for various straight tantala waveguide geometries as a function of wavelength from 800 nm to 5 µm. The waveguide thickness t varies from 0.5 to 1.75 µm in 0.25 µm steps, and the waveguide width w is a constant factor 1.25 times the thickness, $w = 1.25 \times t$. The inset shows a simulation ($t = 1$ µm) of the fundamental transverse-electric mode with labeled cross section dimensions ($t \times w$).

describing the real index of refraction data from 500 nm to 5 µm. The root mean square error of the fit is 0.00057.

Using Eq. (1) as input to finite-element electromagnetic field simulations of nanophotonic waveguides, we calculate the GVD of various cross-sectional geometries of tantala PIC geometries. Figure 1(b) presents a survey of calculated GVD for straight tantala waveguide cross-sectional geometries. The simulated waveguides are a tantala core on silicon dioxide with top and side air-cladding and cross-sectional dimensions of thickness (t) and width (w). Varying the thickness and width of the waveguides makes possible anomalous GVD in various spectral regions. Figure 1(b) shows simulated waveguide thickness from 500 nm to 1750 nm, demonstrating anomalous GVD for light polarized in the chip-plane from the near-infrared into the mid-infrared, and we find that anomalous GVD is possible for straight waveguides with thicknesses of 350 nm and larger, supporting anomalous GVD at a minimum wavelength of ~770 nm.

Using the GVD information, we design and fabricate both supercontinuum generation waveguides and ring resonators. We fabricate the devices by electron-beam lithography and plasma etching of a tantala layer deposited on a thermally oxidized silicon wafer. The top cladding is air, though an oxide cladding is possible [21]. A deep-reactive-ion etch dices the wafer into chips, and an inverse taper to the edge of the devices enhances the fundamental mode overlap for coupling optimization from a lensed fiber [24]. The loss per facet is 3.4 dB, and the waveguide propagation losses are as low as 0.1 dB/cm [21]. In this Letter, we test Eq. (1) with experiments that are highly GVD sensitive, namely the spectral extent of supercontinuum generation and the wavelength dependence of free spectral range

(FSR) in ring resonators. Our results indicate that design of tantala PICs or nonlinear devices are within fabrication tolerances across multiple wafer runs.

PIC waveguides with high nonlinearity are ideal for supercontinuum generation with an input pulsed laser [25]. For comparison, highly nonlinear optical fibers are often used to achieve such spectral broadening in silica [26]. However, PIC waveguides offer much higher nonlinearity, design flexibility, and importantly geometrically tunable GVD [25]. We design and fabricate several tantala supercontinuum waveguides on silicon dioxide with a top and side air-cladding, a waveguide thickness of 570 nm, and an optical path length of 15 mm. We design the devices to offer anomalous GVD in the 1550 nm region and two zero-GVD wavelengths for dispersive wave generation on the short- and long-wavelength side of the pump. To determine the accuracy of our GVD data, we compare the dispersive wave wavelengths of our supercontinuum spectra with theory. The peak wavelength of the dispersive waves depends sensitively on the waveguide GVD and the optical pump power [27,28]. To remove the pump power dependence, we use a power scan technique to record the supercontinuum spectra as a function of pump power in order to extract the zero-pump-power short and long-wavelength dispersive wave wavelengths (λ_{SWDW} and λ_{LWDW}). To vary the GVD, we fabricate several waveguide widths (1.1 to 1.9 µm).

Figure 2(a) presents a schematic of the experimental setup. We use a 100 MHz repetition rate mode-locked laser with 80 fs duration pulses at a central wavelength of 1560 nm. We couple light into the device with a microscope objective and collect the output from the chip with a multi-mode optical fiber, which directs the transmitted light to an optical spectrum analyzer. The fabricated devices demonstrate low optical power dispersive wave wavelength generation. Figure 2(b) shows a sample spectrum collected from a device with waveguide width of 1.6 µm, pumped with an average input pump power of 90 mW (pulse energy 0.9 nJ). We find λ_{SWDW} and λ_{LWDW} by extrapolating a fit of the pump power dependent dispersive wave wavelengths. Figures 2(c) and 2(d) present λ_{SWDW} and λ_{LWDW} as a function of supercontinuum waveguide width. A semi-vectorial method is used to simulate the GVD of the various waveguides to model λ_{SWDW} and λ_{LWDW}. The zero-GVD wavelengths are consistent with the predicted dispersive wave wavelengths at low pump powers in the nonlinear Schrödinger equation [29].

The experimental (dots in Fig. 2) and simulated (lines in Fig. 2) results are in good agreement. The dashed lines in Fig. 2 represent the target geometry (waveguide thickness of 570 nm with various waveguide width), and the solid lines in Fig. 2 signify a variation of $+/-10$ nm in the waveguide thickness, demonstrating agreement within fabrication tolerances. More complex GVD designs using multi-segment waveguides [30] or suspended structures [6] to prevent silica cladding absorption at longer wavelengths [21] can increase the supercontinuum bandwidth.

Ring resonators enhance the intensity of optical fields and provide a discrete set of propagation momenta. Ring resonators are useful for sensitive detection of bioparticles [31] and nonlinear processes, such as four-wave mixing and optical parametric oscillation [32], wavelength translation [1], and soliton optical-frequency-comb generation [2]. To test Eq. (1), we fabricate tantala ring resonators and characterize the wavelength dependence of their FSR. In particular, the integrated dispersion
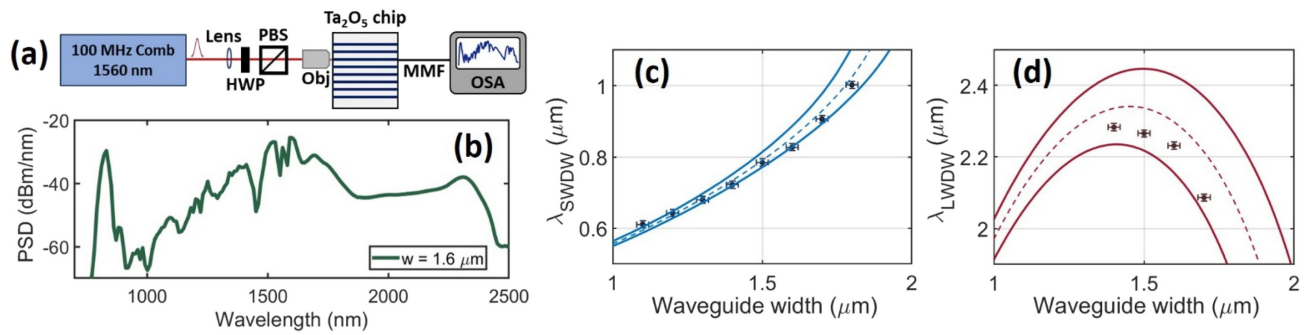

Fig. 2. (a) Experimental setup for supercontinuum measurements. A 100 MHz repetition rate optical frequency comb operating at 1560 nm (<100 mW average power) pumps the tantala device (Ta$_2$O$_5$ chip). A half-wave plate (HWP) and polarizing beam splitter (PBS) prepare the optical power and polarization before the chip. A high-numerical-aperture aspheric lens (Obj) launches light onto the device, a multi-mode optical fiber (MMF) collects the transmitted light, and an optical spectrum analyzer (OSA) monitors the output spectrum. (b) A sample supercontinuum spectrum (power spectral density, PSD) versus wavelength for waveguide width $w = 1.6$ μm. The average input pump power is 90 mW (pulse energy of 0.9 nJ). Measured zero-power dispersive wave wavelengths, (c) λ_{SWDW} and (d) λ_{LWDW}, for various waveguide widths. The data (points) agree with our simulations within fabrication tolerances; the dashed line is the target geometry, and the solid lines denote ±10 nm thickness variation.

$$D_{\text{int}}(\mu) = \nu_\mu - (\nu_0 + \text{FSR} \times \mu) \qquad (2)$$

is a polynomial expansion of the FSR as a function of azimuthal mode μ with respect to a reference optical frequency ν_0 [2]. We calculate D_{int} using a finite-element-method (FEM) mode solver of a tantala ring resonator, including the specific tantala layer thickness, ring resonator waveguide width (RW), and ring radius (RR). We have determined that post-fabrication scanning electron microscope images of the waveguide facets at chip edge are critical to understand the fabricated cross-sectional geometry as compared to the target design. Indeed, our current dry-etching recipe, while providing smooth and vertical side-walls, results in a 50-nm-thick tantala residual pedestal, which we include in our FEM simulations to increase accuracy.

Figure 3 presents measurements of D_{int} versus the resonator azimuthal number as defined in Eq. (2) for several 200 GHz-FSR ring resonators with a RR of 112.5 μm, measured to the center of the ring resonator waveguide. The devices have typical loaded quality factors of 1×10^6. We use lensed fibers to launch light into the on-chip coupling waveguide and to collect light after the resonator. Using a wavelength-tunable, narrow-linewidth, continuous-wave laser and a wavelength meter [Fig. 3(a)], we record the resonant frequencies of as many fundamental transverse-electric modes as possible [Fig. 3(b)]; we determine the resonant frequency by the minimum of resonator laser transmission. We explore the wavelength range of 1510–1620 nm. Figure 3(b) presents D_{int} measurements (color-coded open circles) and simulations (color-coded lines) for four specific settings of RW, namely 1625 nm (blue), 1775 nm (orange), 1925 nm (yellow), and 2075 nm (purple) that are designed to tune the GVD from anomalous to normal. In these data, degeneracies with higher-order transverse modes of the ring resonator perturb the otherwise monotonic behavior about $\mu = 0$. These results demonstrate the efficacy and accuracy of geometric GVD engineering in tantala for various applications.

Lastly, we present designs for octave-bandwidth soliton microcombs in 1 THz-FSR resonators, which we can fabricate [see the image in Fig. 3(c)]. These designs require a high level of GVD engineering and are a benchmark of soliton microcombs as the octave-bandwidth spectra provide f-2f referencing, which is critical for stabilizing the comb [13]. We explore the

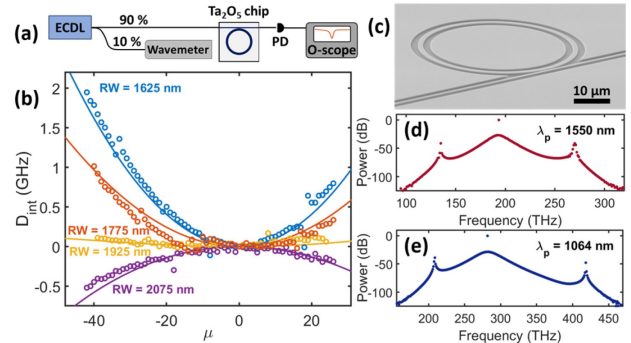

Fig. 3. (a) Schematic of the experimental setup. A widely tunable external cavity diode laser (ECDL) probes the tantala ring resonator (Ta$_2$O$_5$ chip). A fiber coupler sends 10% of the optical power to a wavelength meter (wavemeter) for optical frequency measurement. A photodetector (PD) monitors the laser light transmitted through the ring resonator. Lensed fibers launch light into the device and collect light from the device. (b) The integrated dispersion [D_{int}, Eq. (2)] with a pump wavelength near 1550 nm for 200 GHz-FSR (RR = 112.5 μm) with ring widths 1625, 1775, 1925, and 2075 nm. The data (circles) and simulation (lines) are in good agreement. (c) A scanning electron microscope image of a ring resonator with 1 THz-FSR (RR = 22.5 μm). LLE simulation of an octave-spanning optical frequency comb with pump wavelength (d) 1550 nm (193.4 THz) and (e) 1064 nm (281.8 THz). The ring resonator dimensions, $t \times w$, are 570 nm × 1560 nm (415 nm × 737 nm) for pump wavelength 1550 (1064) nm and RR = 21.25 μm.

theoretical design of octave-bandwidth 1 THz-FSR tantala resonators (RR = 21.25 μm) for two commonly available pump wavelengths in the infrared, 1550 nm and 1064 nm. Both have been used to demonstrate soliton optical frequency Kerr comb generation with 1 THz-FSR devices in silicon nitride [13,33]. Our design procedure uses FEM simulations to choose a waveguide geometry based on our experience of how D_{int} will affect the soliton spectrum. We use the Lugiato–Lefever equation (LLE) to confirm and refine the choice of geometry [34]. We find the ring resonator waveguide cross-sectional dimensions for octave-spanning soliton frequency combs to be $t \times \text{RW} = 570 \text{ nm} \times 1560 \text{ nm}$ for the 1550 nm pump

wavelength and $415\,\text{nm} \times 737\,\text{nm}$ for the 1064 nm pump wavelength. Figures 3(d) and 3(e) present the LLE simulated output soliton optical frequency comb spectra for pump wavelengths of 1550 and 1064 nm, respectively. We model the pump mode as critically coupled with a loaded quality factor of 1×10^6, and the on-chip optical pump power is 40 times the optical parametric oscillation threshold [34]. The peak power of modes near the zero-GVD crossing (dispersive waves) reside at 134.9 and 270.1 THz for the 1550 nm (193.4 THz) pump and 208.7 and 418.2 THz for the 1064 nm (281.8 THz) pump.

In conclusion, we have presented broadband refractive index and extinction coefficient data for tantala. The material provides a broad transparency window from the ultraviolet to the mid-infrared, a high index of refraction, and a large nonlinearity making it an ideal candidate for fabricating linear and nonlinear integrated photonic devices. We provide an analytic third-order Sellmeier equation whose accuracy we verified by its use in designing several chip-scale nonlinear photonic devices. Anomalous GVD is possible from the near- to mid-infrared. We presented octave-spanning supercontinuum waveguides with both short- and long-wavelength dispersive waves and find good agreement between the experimental and simulated results. Additionally, we presented ring resonators with integrated dispersions well predicted by modeling. We show that octave-spanning soliton frequency combs are possible for pump wavelengths 1064 and 1550 nm.

Disclosures. David Carlson is co-founder of Octave Photonics. The remaining authors do not currently have a financial interest in tantala integrated photonics.
